Q: Why is the base64 representation of a uniformly random prime so large? Let  $p$  be a uniformly random prime. The number of possible primes  $p$  is approximately  $1.1 \cdot 10^{23}$ . The number of possible base64 encodings of a prime is  $2^{(p-1)}$  which is small. However, the number of possible random primes is much larger. Can anyone explain why? A: The number of base64 encodings is not small, but  $2^{(p-1)}$  is only the case for odd primes. There is no way to get  $2^{(p-1)}$  base64 encodings for primes of the form  $2 \cdot 2^k - 1$ . The reason for that is the different number of bits needed for the representation. We have  $2^p - 1$  bits needed for the integer  $p$ ,  $2 \cdot 2^k - 1$  bits needed for the base  $2^k$  and 2 bits needed for the sign in base 64, hence we need to round up to the nearest integer. If we have  $2 \cdot 2^k - 1$  bits needed for the integer we need to represent, we need to round up to the nearest power of 2 to represent it. Since  $2^k = 2 \cdot 2^{(k-1)} + 1$ , we need to round up to  $2 \cdot 2^{(k-1)}$  and that is enough for the integer. Since we have 2 bits needed for the sign, we need to round up to the nearest power of 4 and that is enough for the integer. If we have  $2 \cdot 2^k - 1$  bits needed for the integer we need to represent, we need to round up to the nearest power of 4 to represent it. Since  $2^k = 2 \cdot 2^{(k-1)} + 1$ , we need to round up to  $2 \cdot 2^{(k-1)}$  and that is enough for the integer. Since we have 2 bits needed for the sign, we need to round up to the nearest power of 2 and that is enough for the integer. So we always need at least  $2 \cdot 2^{(k-1)}$  bits needed for the integer and that is
